PENULTIMATE GAMMA APPROXIMATION IN THE CLT FOR SKEWED DISTRIBUTIONS

MICHAEL V. BOUTSIKAS

Abstract. Sharp upper bounds are offered for the total variation distance between the distribution of a sum of n independent random variables following a skewed distribution with an absolutely continuous part, and an appropriate shifted gamma distribution. These bounds vanish at a rate $O(n^{-1})$ as $n \to \infty$ while the corresponding distance to the normal distribution vanishes at a rate $O(n^{-1/2})$, implying that, for skewed summands, pre-asymptotic (penultimate) gamma approximation is much more accurate than the usual normal approximation. Two illustrative examples concerning lognormal and Pareto summands are presented along with numerical comparisons confirming the aforementioned ascertainment.

Received July 30, 2014. Revised February 25, 2015.

1. Introduction

The Central limit theorem (CLT) plays a significant role in probability and statistics providing a very simple approximation for the unknown or complicated distribution of a sum of n independent random variables (r.v.’s). It is well-known (via asymptotic expansions, e.g. see Petrov [9]) that the corresponding rate of convergence to the normal distribution is of order $O(n^{-1/2})$ for skewed summands, while it is of order at least $O(n^{-1})$ for smooth symmetric ones. This is due to the fact that the approximation error is of order $O(n^{-(r-1)/2})$ when the standardized distribution of the summands possesses an absolutely continuous part and has the same $r$ $(r \geq 2)$ first moments with the standard normal distribution $\mathcal{N}$. Therefore, when $X_i$’s are smooth and non symmetric, it seems natural to pursue a more accurate than normal approximation by employing an appropriate (preferably infinitely divisible) distribution which has the same first three moments as the summands, i.e. belongs to a class of distributions with location, scale and shape parameters. Perhaps the most tractable such distribution is the (shifted) gamma distribution. A similar observation was also made by Hall [6] who derived (via Edgeworth expansions) asymptotic expansions for the distribution function of the sum of $n$ independent r.v.’s using upper critical points of the chi-square distribution.

The purpose of this paper is to investigate the above idea of pre-asymptotic (penultimate) approximation in the CLT by constructing sharp recursive, closed form and asymptotic bounds for the total variation distance between the distribution of the sum of $n$ independent r.v.’s and an appropriate shifted gamma distribution. More specifically, let $X, X_1, X_2, \ldots$ be independent r.v.’s following a skewed distribution $F$, with $EX = 0, EX^2 = 1, EX^3 = 2/\lambda, EX^4 < \infty$ for some $\lambda > 0$. The case of negatively skewed $X_i$’s can be treated by considering

Keywords and phrases. Central limit theorem, gamma approximation, lognormal sums, rates of convergence, Pareto sums, total variation distance, quantile approximation.

the \(-X_i\)'s. Assume also that \(F\) has an absolutely continuous part. Denoting by \(SG_\theta\) the (shifted by \(-\theta\)) gamma distribution with scale parameter \(\theta\) and shape parameter \(\theta^2\), we show that the total variation distance, \(d(F_n, SG_\gamma, n, \lambda)\), between the distribution \(F_n\) of the standardized sum \(n^{-1/2} \sum_{i=1}^n X_i\) and \(SG_{\gamma, n, \lambda}\), is bounded above by a closed form upper bound \(D_n\) (cf. Thm. 3.2) which is of order \(O(n^{-1})\). It is further proved (cf. Thm. 3.4 and (3.9)) that for a large class of distributions of the summands, the same distance is asymptotically bounded above by

\[
\frac{\|\varphi^{(4)}\|}{16n} \left( 1 + \frac{\langle EX^3 \rangle^2}{2} - \frac{EX^4}{3} \right), \quad \left( \|\varphi^{(4)}\| = 4e^{-3+3\cdot \pi} \frac{\sqrt{1+5+5\cdot \pi + 5+5\cdot \pi}}{\sqrt{3\cdot \pi}} \approx 2.8 \right)
\]

where \(\|\varphi^{(k)}\|\) denotes the \(L_1\) norm of the \(k\)th order derivative of the density \(\varphi\) of the standard normal law \(N\). Note that the corresponding distance between \(F_n\) and \(N\) is (cf. Sirazhdinov and Mamatov [15])

\[
d(F_n, N) \sim \frac{\|\varphi^{(3)}\|}{12\sqrt{n}} |EX^3|, \quad \left( \|\varphi^{(3)}\| = \frac{2+8e^{-3/2}}{\sqrt{2\pi}} \approx 1.51 \right)
\]

(we write \(a_n \sim b_n\) when \(a_n/b_n \to 1\)) and therefore \(F_n\) approaches \(SG_{\gamma, n, \lambda}\) with an approximation error of order \(O(n^{-1})\), while both \(SG_{\gamma, n, \lambda}\) and \(F_n\) converge slower to \(N\), at a rate \(O(n^{-1/2})\). Consequently, in practice it may be preferable to consider a gamma \(SG_{\sqrt{n}, \lambda} = \text{normal} = 2/EX^3\) instead of normal approximation for standardized sums of skewed r.v.'s, especially when the summands follow heavy tailed distributions (but with finite first four moments), and for relatively small and moderate values of \(n\), since for large \(n\), the distributions \(SG_{\sqrt{n}, \lambda}\) and \(N\) are practically identical.

It is worth mentioning that \(F_n\) could also be approximated by appropriate asymptotic expansions with the same \(O(n^{-1})\) or higher order (cf. Petrov [9]). The advantage of our approach is that we use a proper probability distribution \(SG_{\sqrt{n}, \lambda}\) and that we offer explicit (closed form) error bounds whereas the approximation error of the asymptotic expansions do not possess a closed form.

The idea of using the first three or four moments of a sum of r.v.'s in order to approximate its unknown skewed distribution has been employed by many researchers in diverse practical applications. Usually a three or four parameter distribution is proposed in order to fit given data by equating the sample and distribution moments. For example, in the actuarial literature various approximations have been proposed for the distribution of the aggregate claims in a nonlife insurance portfolio. These include shifted gamma, inverse Gaussian (IG), and gamma-IG (e.g. cf. Reijnen et al. [14] and the references therein). The results of the present article theoretically justify the use of a shifted gamma distribution by relying on the first three moments of \(F_n\). It seems that if we could exploit more than the first three moments, we could obtain results with even higher approximation order, but the whole analysis would then be much more complicated.

The organization of the paper is as follows. In the following Section 2 we present necessary notations and auxiliary results, concerning properties (i) of specific probability metrics and (ii) of the standardized gamma distribution. In Section 3 we offer recursive, closed form and asymptotic upper bounds for the total variation distance of interest. Our methodology is based on elementary properties of probability metrics and certain smoothing inequalities (cf. Lem. 2.1). In the second part of this section we demonstrate how the shifted gamma distribution can be used for quantile approximations, and include an example concerning the noncentral chi-squared distribution. Finally, in Section 4, we present two illustrative examples concerning sums of lognormal and Pareto r.v.'s, along with numerical comparisons that reveal the applicability and the performance of our main results.

Note that all the results are formulated using the total variation distance \(d\), but with a proper modification of our methodology, analogous results could also be established for other distances, e.g. for the Kolmogorov distance \(\rho\). Nevertheless, since \(\rho \leq d\), all the upper bounds for \(d\) are also upper bounds for \(\rho\).
2. Preliminaries—Notations

2.1. Probability metrics

We denote by \( \mathcal{L}Y, F_Y \) and \( f_Y \) the distribution, the cumulative distribution function (c.d.f.) and the probability density function (p.d.f.) respectively of a r.v. \( Y \). The total variation and Zolotarev’s distance (\( \zeta \)-metrics of order \( s \in \mathbb{N} \)) between the distributions of two r.v.’s \( W, Y \) are defined respectively by

\[
d(W, Y) = \sup_{A \in \mathcal{B}(\mathbb{R})} |P(W \in A) - P(Y \in A)| = \frac{1}{2} \int_{\mathbb{R}} |f_W(x) - f_Y(x)| \, dx,
\]

\[
\zeta_s(W, Y) = \frac{1}{(s-1)!} \int_{-\infty}^{\infty} \left| \mathbb{E}(W - t)^{s-1} - \mathbb{E}(Y - t)^{s-1} \right| \, dt,
\]

where \( \mathcal{B}(\mathbb{R}) \) denotes the Borel sets of \( \mathbb{R} \), and \( y_{\pm} \overset{\text{def}}{=} (\max\{y, 0\})^s \). The second equality in (2.1) holds true when the densities \( f_W, f_Y \) exist. It follows readily from (2.1) that \( d(\mathcal{L}g(W), \mathcal{L}g(Y)) \leq d(W, Y) \) for every measurable \( g \), and thus the law of \( g(W) \) approximates the law of \( g(Y) \) with (at least) the same accuracy as the law of \( W \) approximates the law of \( Y \). Note also that the distance \( \zeta_s(W, Y) \) can be used only when \( EW_i = EY_i, \ i = 1, 2, \ldots, s - 1 \) (and in this case, it is bounded above by \( (\mathbb{E}|W|^s + \mathbb{E}|Y|^s) / s! \) because otherwise it is not finite. In what follows, for simplicity, we shall write \( Y \) instead of \( \mathcal{L}Y \) in \( d \) or \( \zeta_s \).

The metrics \( d \) and \( \zeta_s \) possess the regularity, the homogeneity and the subadditivity property for independent summands (e.g., see Rachev [11], p. 264). Thus, for \( \zeta_s \) it can be proved that,

\[
\zeta_s \left( \sum_{i=1}^{n} W_i, c \sum_{i=1}^{n} Y_i \right) \leq c^s \sum_{i=1}^{n} \zeta_s(W_i, Y_i), \quad n, s \in \mathbb{N}, \ c > 0,
\]

for independent \( W_i \)'s and independent \( Y_i \)'s. It is also worth mentioning that when the distributions of two r.v.’s \( W, Y \) are \( s \)-convex ordered, the distance \( \zeta_s(W, Y) \) takes on a very simple form. Specifically, if \( W \leq_{s-cx} Y \) for some \( s \in \mathbb{N} \) (i.e. \( \mathbb{E}\phi(W) \leq \mathbb{E}\phi(Y) \) for all regular \( s \)-convex functions \( \phi \) for which the expectations exist; cf. Denuit et al. [4]), then (cf. Boutsikas and Vaggelatou [3]),

\[
\zeta_s(W, Y) = \frac{\mathbb{E}Y^s - \mathbb{E}W^s}{s!}.
\]

The following Lemma 2.1 offers two smoothing inequalities for the metric \( d \). Part (a) has been employed in the past for the derivation of Berry–Esseen-type or Poisson approximation results. Its proof can be found in Rachev [11], p. 274 (see also Boutsikas and Vaggelatou [3] for a more general result). Part (b) was given by Boutsikas [1] while similar inequalities can be found in a number of papers in the literature (e.g. see Rachev [11], p. 325; Zolotarev [17], p. 294 or Rachev and Ruschendorf [12]). Recall that the \( L_1 \) norm of a function \( f \) is \( ||f|| = \int_{-\infty}^{\infty} |f(x)| \, dx \).

Lemma 2.1.

(a) If the r.v.’s \( Y, Y’ \) are independent of the r.v.’s \( W, W’ \) then

\[
d(W + Y, W + Y’) \leq 2d(Y, Y’)d(W, W’) + d(W’ + Y, W’ + Y’).
\]

(b) Let \( Z \) be a r.v., independent of the r.v.’s \( W, Y \), with Lebesgue density \( f_Z \), \( k \)-times differentiable on \( \mathbb{R} \), and denote by \( f_Z^{(k)} \) its \( k \)th order derivative \( (f^0 = f) \). If \( \zeta_k(W, Y) < \infty, \ k \geq 1, \) then,

\[
d(W + Z, Y + Z) \leq \frac{1}{2} \left\| f_Z^{(k)} \right\| \zeta_k(W, Y).
\]
2.2. (ii) The shifted gamma distribution

We denote by \( G(\kappa, \lambda, c) \) the shifted gamma distribution with p.d.f.,

\[
f_G(\kappa, \lambda, c)(x) = \frac{\lambda^\kappa}{\Gamma(\kappa)} (x - c)^{\kappa-1} e^{-\lambda(x-c)}, \quad x \geq c,
\]

where \( \kappa > 0, \lambda > 0 \) and \( c \in R \) are the shape, scale and location parameters respectively. Obviously, the ordinary gamma distribution simply is \( G(\kappa, \lambda, 0) \equiv G(\kappa, \lambda) \) and if a r.v. \( G \sim G(\kappa, \lambda) \) then \( Y = G + c \sim G(\kappa, \lambda, c) \) and for \( k = 1, 2, \ldots, \)

\[
E^k = \frac{\prod_{j=0}^{k-1}(\kappa + j)}{\lambda^k}, \quad EY^k = E(G + c)^k = c^k + \sum_{i=1}^{k} \left( k \frac{\prod_{j=0}^{i-1}(\kappa + j)}{\lambda^i} \right) c^{k-i}.
\]

It is easy to verify that, if the independent r.v.’s \( Y_1, Y_2, \ldots, Y_n \sim G(\kappa, \lambda, c) \) then the sum \( S = \sum_{i=1}^{n} (bY_i + d) \) for \( b > 0, d \in R \), follows the shifted gamma distribution \( G(n\kappa, \lambda/b, n(d + bc)) \). We observe that, if \( X \sim G(\lambda^2, \lambda, -\lambda) \) then

\[
EX = 0, \quad EX^2 = 1, \quad EX^3 = \frac{2}{\lambda}, \quad EX^4 = 3 + \frac{6}{\lambda^2}.
\]

We call the above distribution standardized gamma with parameter \( \lambda \) and denote it by \( SG_\lambda \equiv G(\lambda^2, \lambda, -\lambda) \). It can be easily verified through the CLT that \( SG_\lambda \) converges to the standard normal distribution, \( N \), as \( \lambda \to \infty \).

We also denote by \( \varphi(x) = (2\pi)^{-1/2} e^{-x^2/2} \) the standard normal density, and by \( f^{(k)}_{G(\kappa, \lambda, c)} \) and \( \varphi^{(k)} \) the kth order derivative \( (k = 1, 2, \ldots) \) of \( f_{G(\kappa, \lambda, c)} \) and \( \varphi \) respectively. In the next lemma we offer a simple in form upper bound for the norm \( \|f^{(4)}_{G(\kappa, \lambda, c)}\| = \|f^{(4)}_{G(\kappa, \lambda)}\| \) and derive its asymptotic relation with the norm \( \|\varphi^{(4)}\| \approx 2.80061 \).

**Lemma 2.2.** (a) \( \|f^{(4)}_{G(\kappa, \lambda)}\| < \frac{6}{\pi^2} \lambda^4, \kappa \geq 9 \). (b) \( \kappa^2 \|f^{(4)}_{G(\kappa, \lambda)}\| \to \|\varphi^{(4)}\| \lambda^4 \) as \( \kappa \to \infty \).

**Proof.** See Appendix.

Throughout, we shall assume that \( \sum_{i=1}^{k} a_i = 0 \) when \( j > k \).

3. Main results

3.1. Bounds for the total variation distance

Let \( X, X_1, X_2, \ldots \) be a sequence of independent and identically distributed (i.i.d.) r.v.’s with \( EX = 0, \quad EX^2 = 1, \quad EX^3 = 2/\lambda > 0, \quad EX^4 < \infty \). The restriction of a positively skewed distribution for \( X_i \)’s could be relaxed to \( EX^3 \neq 0 \) because when \( EX^3 < 0 \) we can work with \( -X_i \)’s. Denote by

\[
d_n = d(F_n, SG_{\sqrt{\pi} \lambda}), \quad \lambda = \frac{2}{EX^3},
\]

the total variation distance between the distribution \( F_n \) of \( \frac{1}{\sqrt{n}} \sum_{i=1}^{n} X_i \) and the standardized gamma distribution \( SG_{\sqrt{\pi} \lambda} \). Note that \( SG_{\sqrt{\pi} \lambda} \) has the same first three moments as \( F_n \). The next result offers a recursive bound for the above distance.

**Lemma 3.1.** The total variation distance \( d_n \) between the distribution of \( \frac{1}{\sqrt{n}} \sum_{i=1}^{n} X_i \) and the standardized gamma distribution \( SG_{\sqrt{\pi} \lambda} \), satisfies the following recursive bound

\[
d_n \leq \beta \sum_{j=2}^{n-1} \left\| f^{(4)}_{G((n-j)\lambda^2, \lambda)} \right\| d_{j-1} + \frac{n}{2} \left\| f^{(4)}_{G((n-1)\lambda^2, \lambda)} \right\| \beta + 2d_1d_{n-1},
\]

where \( \beta = \zeta_4(X, SG_{\lambda}) < \infty \).
Proof. Let $Z_1, Z_2, \ldots$ be a sequence of i.i.d. r.v.'s, independent also of $X_i$'s, following the standardized gamma distribution $\mathcal{SG}_\lambda$. From the triangle inequality we deduce that,

\[
d_n = d\left(\sum_{i=1}^n X_i, \sum_{i=1}^n Z_i\right) \leq \sum_{j=1}^n d(W_j + Y_j, W_j + Y_j'),
\]

where $Y_j = X_j + \sum_{i=j+1}^n Z_i$, $Y_j' = \sum_{i=j}^n Z_i$, $W_j = \sum_{i=1}^{j-1} X_i$, $W_j' = \sum_{i=1}^{j-1} Z_i$. The r.v.'s $Y_j, Y_j'$ are independent of $W_j, W_j'$ and by employing Lemma 2.1(a) we get for $n \geq 2, j = 1, 2, \ldots, n$,

\[
d_n \leq \sum_{j=1}^n (2d(Y_j, Y_j')d(W_j, W_j') + d(W_j + Y_j, W_j' + Y_j'))
\]

\[
= 2\sum_{j=2}^{n-1} d\left(X_j + \sum_{i=j+1}^n Z_i, Z_j + \sum_{i=j+1}^n Z_i\right) d_{j-1} + 2d d_{n-1} + \sum_{j=1}^n \left(X_j + \sum_{i \in A_{n,j}} Z_i, \sum_{i=1}^n Z_i\right),
\]

where $A_{n,j} = \{1, \ldots, n\} - \{j\}$. Invoking now Lemma 2.1(b) for $k = 4$, and taking also into account that $\sum_{i=j+1}^n Z_i \sim \mathcal{G}((n-j)\lambda^2, \lambda, -(n-j)\lambda)$, the distances appearing in the sums of (3.2) are bounded above as follows

\[
d\left(X_j + \sum_{i=j+1}^n Z_i, Z_j + \sum_{i=j+1}^n Z_i\right) \leq \frac{1}{2} \left\|f^{(4)}_{\mathcal{G}((n-j)\lambda^2, \lambda)}\right\|_{\mathcal{C}_4}(X_j, Z_j),
\]

\[
d\left(X_j + \sum_{i \in A_{n,j}} Z_i, \sum_{i=1}^n Z_i\right) \leq \frac{1}{2} \left\|f^{(4)}_{\mathcal{G}((n-1)\lambda^2, \lambda)}\right\|_{\mathcal{C}_4}(X_j, Z_j).
\]

The above inequalities, combined with (3.2), readily lead to (3.1). Finally, since $\mathbb{E}X_j^4 = \mathbb{E}Z_j^4, i = 1, 2, 3$, and $\mathbb{E}X_j^4 < \infty$ we have that

\[
\beta = \zeta_4(X_j, Z_j) \leq \frac{\mathbb{E}X_j^4 + \mathbb{E}Z_j^4}{4!} = \frac{\mathbb{E}X_j^4 + 3 + \frac{\delta}{\lambda^2}}{4!} < \infty.
\]

Employing Lemma 2.2(a), the above result implies that, for $\lambda \geq 3$, the total variation distance $d_n$ satisfies the following recursive bound

\[
d_n \leq 6\beta \sum_{j=2}^{n-1} \frac{d_{j-1}}{(n-j)^2} + 3\beta \frac{n}{(n-1)^2} + 2d_1 d_{n-1}, \quad n \geq 2.
\]

(3.3)

Using the bounds (3.1) or (3.3) we can construct recursive upper bounds for $d_n$ in terms of $d_1 = d(X, \mathcal{SG}_\lambda)$ and $\beta = \zeta_4(X, \mathcal{SG}_\lambda)$. For example from (3.3) we can get,

\[
d_2 \leq 6\beta + 2d_1^2, \quad d_3 \leq \left(\frac{9}{4} + 18d_1\right) \beta + 4d_1^3, \quad d_4 \leq \left(6d_1 + 36\beta + 48d_1^2 + \frac{4}{3}\right) \beta + 8d_1^4,
\]

and so forth. If, for instance, $d_1 \leq 0.05$ and $\beta \leq 0.02$, then $d_5 \leq 0.0358, d_{10} \leq 0.0134, d_{30} \leq 0.0033$, and $d_{100} \leq 0.0009$. The recursive bound for $d_n$ that is derived via (3.3) is worse (i.e. larger) but computationally simpler than the one that follows from (3.1). Obviously, a closed form upper bound for $d_n$ would be more convenient. Such a bound is offered (under certain conditions) in the next theorem by employing (3.3).

**Theorem 3.2.** If $d_1 = d(X, \mathcal{SG}_\lambda) < 1/8$, $\lambda \geq 3$ and $\varepsilon = \frac{8d_1}{1 + 8d_1} + 27\beta < 1$, where $\delta = 296/45, \beta = \zeta_4(X, \mathcal{SG}_\lambda)$, then

\[
d_n = d\left(\sum_{i=1}^n X_i, \mathcal{SG}_{\sqrt{n}\lambda}\right) \leq \frac{n}{(n-1)^2} \frac{3\beta}{(1-\varepsilon)} + \frac{1}{2}(2d_1)^n \overset{\text{def}}{=} D_n, \quad n \geq 2.
\]

(3.4)
\textbf{Proof.} We shall use induction. For \( n = 2 \), inequality (3.3) leads to
\[ d_2 \leq 6\beta + 2d_1^2 \leq \frac{6\beta}{1 - \varepsilon} + 2d_1^2 = D_2 \]
and therefore (3.4) is valid for \( n = 2 \). Likewise, for \( n = 3 \), inequality (3.3) along with (3.5) yields
\[ d_3 \leq 6\beta d_1 + 2d_1 d_2 + \frac{9\beta}{4} \leq 6\beta d_1 + 2d_1(6\beta + 2d_1^2) + \frac{9\beta}{4} \]
which is easily verified to be less than or equal to \( D_3 \), and thus (3.4) is valid also for \( n = 3 \). Assume now that (3.4) holds for \( n = 2, 3, \ldots, m - 1 \) \((m \geq 4)\). We shall show that it also holds for \( n = m \). Invoking again (3.3) we get
\[ d_m \leq \frac{6\beta d_1}{(m - 2)^2} + \frac{6\beta}{m - 2} \sum_{j=3}^{m-1} \frac{d_{j-1}}{(m - j)^2} + 2d_1 d_{m-1} + \frac{3\beta m}{(m - 1)^2}, \]
and hence, using the induction assumption (i.e. replacing all \( d_n \), \( n \leq m - 1 \) with their upper bound \( D_n \)), we get
\[ d_m \leq \frac{6\beta d_1}{(m - 2)^2} + \frac{6\beta}{(m - 2)^2} \sum_{j=3}^{m-1} \frac{j - 1}{(m - j)^2} \left( \frac{\beta}{3} + \frac{(2d_1)^{j-1}}{2} \right) + \frac{d_1}{(m - 2)^2} \frac{6\beta}{1 - \varepsilon} + \frac{1}{2} (2d_1)^m + \frac{3\beta m}{(m - 1)^2}, m \geq 4, \]
which is proved to be upper bounded by \( D_m \) as follows. Initially it will be shown that,
\[ \sum_{j=3}^{m-1} \frac{(2d_1)^{j-2}}{(m - j)^2} (1 - \varepsilon) + \frac{(m - \varepsilon)}{(m - 2)^2} \leq \frac{4m}{(m - 1)^2(1 + \delta d_1)}. \]
For \( m = 4 \), the above inequality reduces to
\[ 2d_1 (1 - \varepsilon) + \frac{4 - \varepsilon}{4} \leq \frac{16}{9(1 + \delta d_1)}, \]
which, taking also into account that \( \varepsilon \geq \frac{8d_1}{1 + 8\delta d_1} \), reduces to \( 1 + (2\delta - 16) d_1^2 + \delta d_1 \leq 16/9 \). The latter is easily verified to be true for \( d_1 \leq 2^{-3} \). For \( m \geq 5 \), we invoke Lemma 19 of Boutsikas [1] (for \( k = 4 \)), according to which \( \sum_{j=3}^{m-1} (2^j - (m - j)^2) \leq 2m(m - 1)^{-2}/5, m \geq 5 \). By this inequality and the assumption \( d_1 \leq 2^{-3} \), we ascertain that the left part of inequality (3.7) is bounded above by
\[ \sum_{j=3}^{m-1} \frac{(2d_1)^{j-2}}{(m - j)^2} (1 - \varepsilon) + \frac{m}{(m - 2)^2} \leq \frac{2m}{5(m - 1)^2} \left( 1 - \frac{8d_1}{1 + \delta d_1} \right) + \frac{m}{(m - 2)^2} \leq \frac{4m}{(m - 1)^2(1 + \delta d_1)}, \]
and thus (3.7) is valid for all \( m \geq 4 \).
Next, applying the inequality \( \sum_{j=3}^{m-1} \frac{(j - 1)}{(m - j)^2(2 - j)^2} \leq \frac{9}{2} m(m - 1)^{-2}, m \geq 4 \) (cf. Lem. 18 of Boutsikas [1], for \( k = 4 \)), we get that, for \( m \geq 4 \),
\[ \frac{1}{1 - \varepsilon} \sum_{j=3}^{m-1} \frac{(j - 1) \delta^2}{2(m - j)^2(2 - j)^2} + \frac{3\beta m}{(m - 1)^2} \frac{m(2d_1)^m}{2} \leq \frac{9}{1 - \varepsilon} \frac{m \delta^2}{4(m - 1)^2} + \frac{3\beta m}{(m - 1)^2} \frac{(2d_1)^m}{2}. \]
Adding by parts (3.7) (after multiplying both sides by \( 6\beta d_1/(1 - \varepsilon) \)) and (3.8) we finally get that (3.6) is bounded above by \( D_m \) and the proof is completed. \( \square \)
Remark 3.3. It is worth mentioning that the distance $\beta = \zeta_4(X, \mathcal{S}\mathcal{G}_\lambda)$ appearing in the above expressions can be easily evaluated when $X \leq \varepsilon X$ or $Y \leq \varepsilon X$ (cf. (2.3)), where $Y \sim \mathcal{S}\mathcal{G}_\lambda$, since in this case,

$$
\beta = \frac{|EY^4 - EX^4|}{4!} = \frac{1}{4!} \left[ 3 + \frac{6}{\lambda^2} - EX^4 \right] = \frac{1}{8} \left[ 1 + \frac{(EX^3)^2}{2} - \frac{EX^4}{3} \right].
$$

(3.9)

In the following theorem we prove an asymptotic result for the total variation distance between the distribution of $n^{-1/2} \sum_{i=1}^n X_i$ and $\mathcal{S}\mathcal{G}_{\sqrt{n}\lambda}$ that holds true when the common c.d.f. $F$ of $X_i$’s has an absolutely continuous part. Its proof is based on Lemma 3.1 and Theorem 3.2 but the additional assumptions imposed in Theorem 3.2 are no longer necessary. Note that every c.d.f. $F$ can be written in the form $F = pF_{ac} + (1-p)F_s$, $p \in [0,1]$ where $F_s$ is a singular c.d.f. (discrete and/or singular continuous) and $F_{ac}$ is an absolutely continuous c.d.f. A c.d.f. $F$ has an absolutely continuous part when $p > 0$.

Theorem 3.4. If the distribution of $X_i$’s has an absolutely continuous part, then

$$
\limsup_{n \to \infty} n \cdot d \left( \frac{1}{\sqrt{n}} \sum_{i=1}^n X_i, \mathcal{S}\mathcal{G}_{\sqrt{n}\lambda} \right) \leq \frac{1}{2} \left\| \varphi^{(4)} \right\| \beta.
$$

where $\beta = \zeta_4(X, \mathcal{S}\mathcal{G}_\lambda)$.

Proof. Consider the sequence of i.i.d. r.v.’s $X_i, r = \frac{1}{\sqrt{r}} \sum_{j=(i-1)r+1}^i X_j$, $i = 1, 2, \ldots$ for some positive integer $r$. It is easy to verify that $E X_i, r = 0, EX_i \lambda^2 = 2/\lambda_r > 0, EX_i^4 < \infty$ where $\lambda_r = \lambda^r$. Applying (3.1) for the sequence of r.v.’s $X_1, r, X_2, r, \ldots$ along with Lemma 2.2(a) we get

$$
d_{m,r} \leq 6\beta_r \sum_{j=2}^{m-1} \frac{d_{j-1,r}}{(m-j)^2} + \left\| \varphi^{(4)} \right\| \frac{m\beta_r}{2} + 2d_{1,r}d_{m-1,r}, \quad m \geq 2,
$$

(3.10)

where, also using known properties of $\zeta_4$ (cf. (2.2)),

$$
\beta_r = \zeta_4(X_1, r, \mathcal{S}\mathcal{G}_{\sqrt{\lambda}r}) = \zeta_4 \left( \frac{1}{\sqrt{r}} \sum_{i=1}^r X_i, \mathcal{S}\mathcal{G}_{\sqrt{\lambda}} \right) \leq \zeta_4(X_1, \mathcal{S}\mathcal{G}_{\sqrt{\lambda}}) = \frac{\beta_r}{r}.
$$

$$
d_{m,r} = d \left( \frac{1}{\sqrt{m}} \sum_{i=1}^m X_i, \mathcal{S}\mathcal{G}_{\sqrt{\lambda}} \right) = d \left( \frac{1}{\sqrt{m}} \sum_{i=1}^m X_i, \mathcal{S}\mathcal{G}_{\sqrt{\lambda}} \right) = d_{mr}, \quad m \geq 1.
$$

Moreover, applying Theorem 3.2 for the sequence $X_1, r, X_2, r, \ldots$, we also get the inequality

$$
d_{n,r} \leq \frac{n}{(n-1)^2} \frac{3\beta_r}{(1 - \varepsilon_r)} + \frac{1}{2} (2d_{1,r})^n, \quad n \geq 2.
$$

(3.11)

provided that $\varepsilon_r = \frac{8d_{1,r}}{3d_{m,r}} + 27\beta_r < 1$ ($\delta = 296/45$), $\lambda_r \geq 3$ and $d_{1,r} < 1/8$. Combining now inequalities (3.10) and (3.11) we deduce, for $m \geq 3$,

$$
d_{m,r} \leq \frac{6\beta_r d_{1,r}}{(m-2)^2} + \frac{6\beta_r \sum_{j=3}^{m-1} \frac{(j-1)3\beta_r}{(j-2)^2(1 - \varepsilon_r)} + (2d_{1,r})^{j-1}}{(m-j)^2} + \left\| \varphi^{(4)} \right\| \frac{m\beta_r}{2} + 2d_{1,r} \left( \frac{3\beta_r}{(m-2)^2(1 - \varepsilon_r)} + \frac{(2d_{1,r})^{m-1}}{2} \right).
$$

(3.12)
Applying the inequality \( \sum_{j=3}^{m-1} \frac{(i-1)}{(m-j)^2}r^2 \leq \frac{9}{2}m(m-1)^{-2}, m \geq 4 \) (cf. Lem. 18 of Boutsikas [1], for \( k = 4 \)) and taking into account that \( \beta_r = \beta/r, d_{ir} = d_{ir}, \lambda_r = \lambda/\sqrt{r} \), inequality (3.12) readily leads to

\[
d_{mr} \leq \frac{6d_r\beta}{r(m-2)^2} + \frac{81m\beta^2}{r^2(1-\varepsilon_r)}(m-1)^{-2} + 3\frac{\beta}{r} \sum_{j=3}^{m-1} \frac{(2d_r)_{j-1}}{(m-j)^2} \left[ f_{G((m-1)\lambda^2r,\lambda/\sqrt{d_r})} \right] \left[ f_{\tilde{G}(\beta)} \right] m\beta \frac{2}{2r} + \frac{6d_r(m-1)\beta}{r(m-2)^2(1-\varepsilon_r)} + \left( \frac{2d_r}{2} \right)^m, \tag{3.13}
\]

for \( m \geq 4, r \geq 1 \), provided that \( \varepsilon_r = \frac{3d_r}{1+6d_r} + 27\beta r < 1, \lambda/\sqrt{r} \geq 3 \) and \( d_r < 1/8 \).

Observe now that every integer \( n \) can be written in the form \( n = mr + j \) with \( m = r = \lfloor \sqrt{n} \rfloor \) (the integer part of \( \sqrt{n} \)) and some integer \( j \in \{0, 1, \ldots, 2\lfloor \sqrt{n} \rfloor \} \). If \( Z_1, Z_2, \ldots \) is a sequence of i.i.d. r.v.'s, independent also of \( X_i \)'s, following the standardized gamma distribution \( SG_{\lambda} \) then from the triangle inequality we deduce that

\[
d_n = d \left( \sum_{i=1}^{mr+j} X_i, \sum_{i=1}^{mr+j} Z_i \right) \leq d \left( \sum_{i=1}^{mr+j} X_i, \sum_{i=1}^{mr} Z_i + \sum_{i=mr+1}^{mr+j} X_i \right) + d \left( \sum_{i=1}^{mr} Z_i + \sum_{i=mr+1}^{mr+j} X_i, \sum_{i=1}^{mr+j} Z_i \right). \tag{3.14}
\]

Invoking the regularity property of the metric \( d \) we realize that the first term in the right part of (3.14) is less than or equal to \( d_{mr} \). Applying also Lemma 2.1(b) for the second term in the right part, and then employing Lemma 2.2(a) (for \( mr\lambda^2 \geq 9 \)) and the subadditivity property of the metric \( \zeta_s \), we get

\[
d_n \leq d_{mr} + \frac{1}{2} \left\| f_{G((mr\lambda)^2,\lambda)} \right\| \zeta_4 \left( \sum_{i=mr+1}^{mr+j} X_i, \sum_{i=mr+1}^{mr+j} Z_i \right) \leq d_{mr} + \frac{3n - 1}{2mr} \sum_{i=mr+1}^{mr+j} \zeta_4(X_i, Z_i) \tag{3.15}
\]

Notice also that \( d \left( \frac{1}{\sqrt{r}} \sum_{i=1}^{r} X_i, N \right) \to_{r \to \infty} 0 \), provided that \( \mathcal{L}X \) has an absolutely continuous part (see Prokhorov [10]) and thus, as \( r \to \infty \),

\[
d_r = d \left( \frac{1}{\sqrt{r}} \sum_{i=1}^{r} X_i, SG_{\lambda/\sqrt{d_r}} \right) \leq d \left( \frac{1}{\sqrt{r}} \sum_{i=1}^{r} X_i, N \right) + d \left( N, SG_{\lambda/\sqrt{d_r}} \right) \to 0. \tag{3.16}
\]

Therefore, for large enough \( n \) such that \( m \geq 4, \varepsilon_r < 1, \lambda/\sqrt{r} \geq 3, d_r < 1/8 \), and \( mr\lambda^2 \geq 9 \), where \( m = r = \lfloor \sqrt{n} \rfloor \), relations (3.13) and (3.15) yield

\[
n \left( d_n \right) \leq \frac{6d_r\beta}{r(m-2)^2} + \frac{81n\beta^2}{r^2(1-\varepsilon_r)(m-1)^{-2}} + 3\frac{\beta}{r} \sum_{j=3}^{m-1} \frac{(2d_r)_{j-1}}{(m-j)^2} \left[ f_{G((m-1)\lambda^2r,\lambda/\sqrt{d_r})} \right] \left[ f_{\tilde{G}(\beta)} \right] m\beta \frac{2}{2r} + \frac{6d_r(m-1)\beta}{r(m-2)^2(1-\varepsilon_r)} + \left( \frac{2d_r}{2} \right)^m, \tag{3.17}
\]

Using (3.16) and the fact that \( n^2 \left\| f_{G((m-1)\lambda^2r,\lambda/\sqrt{d_r})} \right\| = \lambda^4 r^2 n^2 \left\| f_{G((m-1)\lambda^2r,\lambda/\sqrt{d_r})} \right\| \to_{n \to \infty} \left\| \varphi^{(4)} \right\| \) (cf. Lem. 2.2(b) and relation (A.1)), it can be verified that the right part of inequality (3.17), tends to \( \frac{1}{2} \left\| \varphi^{(4)} \right\| \beta \) as \( n \to \infty \) and hence finally

\[
\limsup_{n \to \infty} n \left( d_n \right) \leq \frac{1}{2} \left\| \varphi^{(4)} \right\| \beta. \tag*{\Box}
\]
From the above theorem it is evident that, when $\mathcal{L}X$ possesses an absolutely continuous part, the distribution of $\frac{1}{\lambda_n} \sum_{i=1}^n X_i$ approaches $SG_G \sqrt{\lambda_n}$, $\lambda = 2/EX^3$, and consequently the distribution of the sum $\sum_{i=1}^n Y_i$ of the non-standardized $Y_i = \mu + \sigma X_i, i = 1, 2, \ldots, n$, can be approximated by $G(n\lambda^2, 2\lambda_n, n\mu - \sigma \lambda)$ with an approximation error of order $O(n^{-1})$. In particular, $d_n$ is asymptotically upper bounded by

$$D_n^* = \frac{1}{2n} \|\phi^{(4)}\| \beta = \left(\frac{\|\phi^{(4)}\|}{16n}\right) \left(1 + \frac{(EX)^2}{2} - \frac{EX^4}{3}\right),$$

where $\|\phi^{(4)}\| \approx 2.8006$, and the last equality holds true when $X \leq_4 \xi \mathcal{G}_\lambda$ or $X \geq_4 \xi \mathcal{G}_\lambda$. It is noteworthy that, at least in the cases treated in the last section, the distance $d_n$ is almost equal to its asymptotic bound $D_n^*$, sometimes even for relatively small values of $n$ (see Tabs. 3, 4, 5). Note that the closed form upper bound $D_n \approx \frac{3}{(1 - \varepsilon_n)^m} \beta$ that follows from Theorem 3.2 is usually 2 to 4 times larger than $D_n^*$.

**Remark 3.5.** In view of the conditions imposed in Theorem 3.2, the bound (3.4) is valid when $\lambda \geq 3$ and the distances $\beta = \zeta_4(X, \mathcal{G}_\lambda)$ and $d_n = d(X, \mathcal{G}_\lambda)$ are relatively small, that is, the distribution $\mathcal{L}X$ of the summands is relatively close to $\mathcal{G}_\lambda$. However, we can always overcome these requirements as was accomplished in the proof of Theorem 3.4, provided that $\mathcal{L}X$ has an absolutely continuous part. More specifically, we can apply Theorem 3.2 for the i.i.d. r.v.'s $X_{i,r} = \frac{1}{\sqrt{r}} \sum_{j=(r-1)r+1}^r X_j, i = 1, 2, \ldots$ for appropriately large $r$. For these r.v.'s we observe that $EX_{i,r} = 0, EX^2_{i,r} = 1, EX^3_{i,r} = 2\lambda r^{-1}, \lambda_r = \sqrt{r}X^3$ and $d_{i,r} = d(X_{i,r}, \mathcal{G}_\lambda) = O(n^{-1})$ (cf. Thm. 3.4) and $\beta_r = \zeta_4(X_{i,r}, \mathcal{G}_\lambda) \leq \frac{1}{r} \beta$ (see (2.2)). Therefore, we can always find $r$ large enough such that $d_{1,r} < 1/8, \lambda_r \geq 3$ and $\varepsilon_r = \frac{8d_{1,r}}{1 + 8d_{1,r}} + 27\beta_r r < 1$, and employ Theorem 3.2 for the sequence $X_{i,r}, i = 1, 2, \ldots$, to deduce for $d_n, n = rm$, the inequality

$$d_n = d \left(\frac{1}{\sqrt{m}} \sum_{i=1}^m X_{i,r}, \mathcal{G}_\sqrt{rm \lambda}\right) = d \left(\frac{1}{\sqrt{m}} \sum_{i=1}^m X_{i,r}, \mathcal{G}_\sqrt{m \lambda}\right) \leq \frac{m \beta_r}{(m-1)^2} \left(1 - \varepsilon_r\right) + \frac{1}{2} (2d_{1,r})^m, \quad \text{for } m \geq 2. \quad (3.18)$$

### 3.2. Distribution and quantile approximation

In this subsection we demonstrate how we can use the above shifted gamma distribution to approximate the c.d.f. and the $a$-quantile of $\sum_{i=1}^n U_i$, where $U_1, U_2, \ldots$ is a sequence of positively skewed i.i.d. r.v.s. Let $\mu = EU_i, \sigma^2 = \nu U_i$, and $X_i = (U_i - \mu)/\sigma, i = 1, 2, \ldots$. Let also $G$ be a r.v. that follows a $G(\lambda_n^2, \lambda_n)$ distribution with $\lambda_n = \lambda/\sqrt{n} = 2\sqrt{n}/EX^3$. It follows that $G - \lambda_n \sim G(\lambda_n^2, \lambda_n, \lambda_n) = SG_G \sqrt{\lambda_n}$, Therefore, invoking Theorem 3.2 and the properties of the total variation distance (cf. preliminaries section) we deduce that, under appropriate conditions,

$$\left| P \left( g \left(\frac{1}{\sqrt{n}} \sum_{i=1}^n X_i \right) \in A \right) - P \left( g \left(G - \lambda_n \right) \in A \right) \right| \leq D_n \quad (3.19)$$

for every Borel set $A$ and every measurable function $g$. By choosing $A = (-\infty, (x - n\mu)/(\sigma \sqrt{n}))$ and $g(t) = t$, we readily get from (3.19) that, for every $x \in R$,

$$\left| P \left( \sum_{i=1}^n U_i \leq x \right) - F_G(\lambda^2, \lambda_n) \left(\frac{x - n\mu}{\sigma \sqrt{n}} + \lambda_n\right) \right| \leq D_n, \quad \lambda_n = \frac{2\sqrt{n}}{EX^3}, \quad (3.20)$$

where $F_G(\lambda^2, \lambda_n)$ denotes the c.d.f. of a gamma distribution with shape parameter $\lambda^2$ and scale parameter $\lambda_n$. Hence, the c.d.f. of $\sum_{i=1}^n U_i$ can be approximated at $x$ by $F_G(\lambda^2, \lambda_n)((x - n\mu)/(\sigma \sqrt{n}) + \lambda_n)$. Recall that the corresponding Normal approximation is $\Phi((x - n\mu)/(\sigma \sqrt{n})).$ Utilizing the above inequality (3.20) we can also extract an approximation for the $a$-quantile of $\sum_{i=1}^n U_i$. Indeed, if we denote by $x_a$ the upper $(1 - a)$-level
critical point of this distribution, i.e. \( P(\sum_{i=1}^{n} U_i \leq x_a) = 1 - a \), then, by setting \( x = x_a \) in (3.20) we readily deduce that,

\[
n\mu + \sigma \sqrt{n} \left( F^{-1}_{\lambda^2, \lambda_n} \left( 1 - a - D_n \right) - \lambda_n \right) \leq x_a \leq n\mu + \sigma \sqrt{n} \left( F^{-1}_{\lambda^2, \lambda_n} \left( 1 - a + D_n \right) - \lambda_n \right),
\]

where \( F^{-1}_{\lambda^2, \lambda_n} \) is the inverse of the c.d.f. \( F_{\lambda^2, \lambda_n} \). The above implies that the upper \((1 - a)\)-level critical point (referred to as Value at Risk when \( \sum_{i=1}^{n} U_i \) expresses the total loss on a financial portfolio) can be approximated by,

\[
x_a \approx x_a^{SG} = n\mu + \sigma \sqrt{n} \left( F^{-1}_{\lambda^2, \lambda_n} \left( 1 - a \right) - \lambda_n \right). \tag{3.21}
\]

The respective normal approximation is \( x_a \approx x_a^N = n\mu + \sigma \sqrt{n} z_a \), where \( z_a = \Phi^{-1}(1 - a) \).

**Example** (Noncentral chi-squared distribution – numerical comparison with the results of Hall [6]). As already noted in the introduction, Hall [6] has also proposed a penultimate approximation in the CLT, by employing an appropriate (standardized) chi-squared distribution. Hall’s approximation yields an error of the same order as our bound, \( D_n \) (see (3.20)), while his approach is based on asymptotic expansions with remainder terms that are expressed via \( o(n^{-p}) \). As an application, he proposed an approximation for the quantiles of the noncentral chi-squared distribution and proceeded to a numerical evaluation of his approximation for specific values of the parameters (cf. Table 1 in Hall [2]). In what follows we shall also treat the same problem in order to illustrate the quantile approximation presented above and also for comparison reasons.

Let \( Z_1, Z_2, \ldots, Z_n \) be independent standard normal r.v.’s and set \( U_i = (Z_i + \sqrt{\xi/n})^2, i = 1, 2, \ldots, n \). It is well-known that the r.v. \( \sum_{i=1}^{n} U_i \) follows a noncentral chi-squared distribution with \( n \) degrees of freedom and noncentrality parameter \( \xi > 0 \). It can be easily verified that

\[
\mu = \mathbb{E}U_i = 1 + \frac{\xi}{n}, \quad \sigma^2 = \mathbb{V}U_i = 2 \left( 1 + \frac{2\xi}{n} \right), \quad \mathbb{E}X_i^3 = \mathbb{E} \left( \frac{U_i - \mu}{\sigma} \right)^3 = \frac{2^{3/2}(1 + 3\xi/n)}{(1 + 2\xi/n)^{3/2}}.
\]

Thus, the upper \((1 - a)\)-level critical point, \( x_a \), of the noncentral chi-squared distribution \((n, \xi)\) can be approximated by (cf. (3.21)),

\[
x_a^{SG} = n + \xi + \sqrt{2(n + 2\xi)} \left( F^{-1}_{\lambda^2, \lambda_n} \left( 1 - a \right) - \lambda_n \right), \quad \lambda_n = \frac{2\sqrt{n}(1 + 2\xi/n)^{3/2}}{2^{3/2}(1 + 3\xi/n)}.
\]

We numerically compare the above approximating formula, \( x_a^{SG} \), with the one proposed by Hall (denoted by \( x_a^H \)). The corresponding values are shown in Table 1, where we have also included the exact value of \( x_a \) (up to 4 decimals) for \( a = 0.1 \). The first four rows of this table are the same as in Hall [6] (recalculated). The last two rows exhibit the performance of the shifted gamma approximation, \( x_a^{SG} \), and the usual normal approximation, \( x_a^N = n\mu + \sigma \sqrt{n} z_a \).

In Table 2 we numerically compare the same quantities, but this time we choose a very small \( a \) in order to show the performance of \( x_a^H, x_a^{SG} \) and \( x_a^N \) further in the right tail of the noncentral \( \chi^2 \) distribution.

From the above tables it is evident that the shifted gamma approximation, \( x_a^{SG} \), exhibits a very good overall performance in the right tail, also slightly better than \( x_a^H \). The advantage of \( x_a^{SG} \) is that it relies on the upper critical points of the (central) chi-squared distribution which sometimes are more readily available (e.g. when a computer is not ready for use). The second table also shows that the usual normal approximation is remarkably poor at the far right tail of this distribution and in practice should be avoided.

### 4. Applications

#### 4.1. The distribution of the sum of lognormal r.v.’s

As a first simple example we consider the case where the summands follow a lognormal distribution, \( \mathcal{LN}(\mu, \sigma) \). This distribution appears in numerous applications in various research areas (e.g. finance, actuarial theory,
formally, we consider independent r.v.’s
therefore normal approximation may not be so efficient, especially for moderate or small values of
(reliability theory, telecommunications, biology, hydrology, etc.). The distribution of the sum of i.i.d. lognormally
distributed r.v.’s has no closed-form analytic expression and therefore an effective approximation seems essential (e.g. see Mehta et al. [8], Dufresne [5] and the references therein). Lognormal is a skewed distribution and
to compute that
Note that the distribution of
Lognormal or normal is a skewed distribution and
Approximating the upper critical points of the noncentral
We shall work with the standardized i.i.d. r.v.’s
and
for which we have \( \mathbb{E}X_i = 0, \mathbb{E}X_i^2 = 1 \) and

\[
\mathbb{E}X_i^3 = (2 + e^{\sigma^2})\sqrt{e^{\sigma^2} - 1} = \frac{2}{\lambda}, \quad \mathbb{E}X_i^4 = -3 + e^{2\sigma^2}(3 + e^{\sigma^2}(2 + e^{\sigma^2})).
\]

Note that the distribution of \( X_i \) has only one parameter, \( \sigma \) (does not depend on \( \mu_i \)). It can be easily checked numerically (at least for \( \sigma < 1 \)) that \( \mathbb{C}X_i \geq 0, \) \( S\mathcal{L}_{\lambda} \). Indeed, according to the Karlin–Novikoff criterion (cf. Karlin and Novikoff [7]), the corresponding p.d.f.’s cross each other at most 4 times and after their last crossing (at right) the p.d.f. of \( X_i \) is above the p.d.f. of \( S\mathcal{L}_{\lambda} \). Thus (cf. (3.9)),

\[
\beta = \zeta_4(X_i, S\mathcal{L}_{\lambda}) = \frac{\mathbb{E}X_i^4 - (3 + \frac{6}{\lambda^2})}{4!} = \frac{2e^{4\sigma^2} + e^{3\sigma^2} - 3e^{2\sigma^2}}{2 \cdot 4!}.
\]

Employing Theorem 3.4 we derive that

\[
\limsup_{n \to \infty} n \, d_n \leq \frac{\|\varphi(4)\| \beta}{2} = 2e^{\frac{2\sigma^2}{\lambda^2}} \sqrt{\frac{3\sqrt{3} - \sqrt{\sqrt{3} + 3\sqrt{3} + 3\sqrt{3}}}{\pi^3}} \frac{2e^{4\sigma^2} + e^{3\sigma^2} - 3e^{2\sigma^2}}{2 \cdot 4!} = n d^*_n,
\]

and therefore \( d^*_n \) is a simple in form asymptotic bound for \( d_n = d(n^{-1/2} \sum_{i=1}^n X_i, S\mathcal{L}_{\lambda}) \), \( \lambda = 2/\mathbb{E}X_i^3 \). Hence, when \( \mu_i = \mu \), the distribution of \( \sum_{i=1}^n L_i \) can be approximated by \( \mathcal{G}(nL^2, \lambda/\sigma_L, n\mu_L - n\lambda\sigma_L) \), where \( \mu_L = \mathbb{E}L_i = e^{\mu+\sigma^2/2} \), and \( \sigma_L = \sqrt{\mathbb{V}L_i} = \sqrt{e^{\sigma^2} - 1}e^{\mu+\sigma^2/2} \). If, for example, \( \sigma = 0.6 \) and \( n = 30 \), we readily compute that \( S\mathcal{L}_{\lambda, \mu} \approx S\mathcal{L}_{1.6, 2.9} \), and \( d^*_n \approx 0.0050 \) while the corresponding distance from the normal distribution is \( d^*_n = d(n^{-1/2} \sum_{i=1}^n X_i, N) \approx 0.0519 \) (cf. Eq. (1.1)).

</table>

Furthermore, should we wish to construct an explicit upper bound for $d_n$ we can use Theorem 3.2. For this purpose we need to compute the value of $d_1 = d(X_1, SG_\lambda)$. For illustration purposes we shall examine two cases: (i) $\sigma = 0.2$ (where Thm. 3.2 is readily applicable) and (ii) $\sigma = 0.5$ (where we have to follow the procedure described in Rem. 3.5).

(i) For $\sigma = 0.2$, we compute $\lambda \approx 3.25577$ (cf. (4.1)), $\beta \approx 0.00468036$ (cf. (4.2)), $d_1 \approx 0.0065625$ (cf. (2.1)) and $\varepsilon = 8d_1(1 + \frac{2d_1}{n})^{-1} + 27\beta \approx 0.176698 < 1$. Since $\varepsilon < 1, \lambda > 3$ and $d_1 < 1/8$, we can apply Theorem 3.2, and get

$$d_n = d\left(\frac{1}{\sqrt{n}} \sum_{i=1}^{n} X_i, SG_\sqrt{n}\lambda\right) \leq D_n = \frac{n}{(n-1)^2 (1 - \varepsilon)} \frac{3\beta}{(1 - \varepsilon)^2} + \frac{(2d_1)^n}{2}, \quad n \geq 2.$$  

The performance of the above bound, $D_n$, is shown in Table 3, where we have also included the asymptotic upper bound $D_\ast n \approx 0.00655391 \times n^{-1}$, as well as the exact values of the distances $d_n$ and $d_n^U$, which were evaluated numerically ($\tilde{n}a$ numerical integration of the $n$-fold convolution integral). In order to show the performance of the shifted gamma approximation at the far right tail of the distribution, we present in the same table the Monte Carlo estimated values, $\hat{x}_a$, of the upper 99.9%-level critical point $x_a$ of the distribution of $\sum_{i=1}^{n} L_i$ for $\mu_i = 0, \sigma = 0.2$ (based on $10^6$ samples), along with its shifted gamma $(x_a^{SG}, \text{cf. (21)})$ and its usual normal approximation $(x_a^{N})$. Note that when $\sum_{i=1}^{n} L_i$ expresses the total loss on a portfolio of $n$ financial assets, $x_a$ is also referred to as Value at Risk. The approximation through the chi-square distribution suggested by Hall [6] is almost identical to $x_a^{SG}$ (they differ only beyond the 2nd decimal place) and thus it is not included in the table. All computations were performed using Wolfram Mathematica Software.

(ii) For $\sigma = 0.5$, we similarly compute $\lambda \approx 1.14273, \beta \approx 0.0543208, d_1 \approx 0.087255$ and $\varepsilon \approx 1.91016$. In this case we cannot apply directly Theorem 3.2 since $\varepsilon > 1$ and $\lambda < 3$. According to Remark 3.5 we can overcome this by considering the r.v.’s $X_1, r = r^{-1/2} \sum_{j=i(r-1)+1}^{i(r-1)+n} X_j, i = 1, 2, \ldots$ By choosing $r = 8$ we have that

$$\lambda_r = \lambda r^{1/2} \approx 3.23214, \quad d_{1,r} = d(X_1, r, SG_{\lambda r}) \approx 0.008691, \quad \beta_r = \frac{\beta}{r} \approx 0.0067901,$$

and thus $\varepsilon_r \approx 0.249101$. Now the conditions $\varepsilon_r < 1, \lambda_r > 3, d_{1,r} < 1/8$ are satisfied for the sequence $X_{1,r}, X_{2,r}, \ldots$, and Theorem 3.2 leads to (cf. (3.18))

$$d_n \leq D_{m,r} = \frac{m}{(m-1)^2} \frac{3\beta}{(1 - \varepsilon_r)^2} + \frac{1}{2}(2d_{1,r})^m, \quad n = mr, \quad m \geq 2.$$  

Similarly to (i) we construct the following Table 4.

From Tables 3 and 4 we observe that the asymptotic upper bound $D_\ast n$ is very close to the true value of $d_n$ even for small values of $n$. It is evident that the $n$-fold convolution of the lognormal distribution can be efficiently approximated by the standardized gamma distribution $SG\lambda$, with $\lambda = 2(\mathbb{E}X_1^3)^{-1} = 2(2 + e^{\sigma^2})^{-1}(e^{\sigma^2} - 1)^{-1/2}$, while the normal approximation performs rather poorly. The performance of the approximation $x_a^{SG}$ for the upper 99.9%-level critical point $x_a$ seems also quite satisfactory, much superior to $x_a^{N}$. 

4.2. The distribution of the sum of Pareto r.v.’s

In this example we consider the case where the independent summands follow a Pareto distribution \( P(a) \) with p.d.f.

\[
f(x) = \frac{\alpha}{x^{\alpha+1}}, \ x > 1.
\]

This distribution appears in many applications (economics, actuarial theory, hydrology, reliability theory, etc.). It is also used to model the tail of heavy tailed distributions in extreme value theory. For example, peaks over high thresholds of heavy tailed r.v.’s (having regularly varying tails with index \(-\alpha\)) follow asymptotically (when the threshold tends to infinity) a Pareto distribution with parameter \( \alpha \). Thus, the sum of exceedances of i.i.d. heavy tailed r.v.’s above a high threshold can be considered as a sum of i.i.d. Pareto r.v.’s. The \( k \)th order moment of \( P(a) \) is finite only when \( k < \alpha \) and therefore we assume \( \alpha > 4 \) so that \( P(a) \) possesses finite first four moments. Note that, when \( 0 < \alpha < 2 \), the distribution of the sum of Pareto r.v.’s is usually approximated through the generalized CLT by a \( \alpha \)-stable distribution (e.g. see Zaliapin, Kagan and Schoenberg [16] and the references therein) while for \( \alpha \) integer the distribution of this sum can be approximated by inverting its Laplace transform (see Ramsay [13]).

In what follows we will examine a penultimate gamma distribution approximation when \( \alpha > 4 \). Let \( Y, Y_1, Y_2, \ldots, \) be independent r.v.’s following a \( P(a) \) distribution. The moments of \( Y \) are \( \mathbb{E} Y^k = \frac{\alpha^k}{\alpha - k}, k < \alpha \).

We shall work with the standardized r.v.’s \( X_i = (Y_i - \mathbb{E} Y_i)/\sqrt{\mathbb{V} Y_i} \). Obviously, \( \mathbb{E} X_i = 0, \mathbb{E} X_i^2 = 1 \) and also

\[
\mathbb{E} X_i^3 = \frac{2(\alpha + 1)\sqrt{\alpha - 2}}{\sqrt{\alpha(\alpha - 3)}}, \quad \mathbb{E} X_i^4 = \frac{3(\alpha - 2)(2 + \alpha + 3\alpha^2)}{\alpha(\alpha - 3)(\alpha - 4)}.
\]

Again, it can be easily checked numerically (at least for \( \alpha < 10 \)) that \( SG_{\lambda} \geq_{1-cx} \mathcal{L} X_i \). Therefore,

\[
\beta = \zeta_4(X_i, SG_{\lambda}) = \frac{\mathbb{E} X_i^4 - (3 + \frac{6}{\lambda^2})}{4!} = \frac{(\alpha - 1)^3}{2(\alpha(\alpha - 3)^2)}.
\]

We can now approximate \( \frac{1}{n} \sum_{i=1}^{n} X_i \) by \( SG_{\sqrt{n} \lambda} \), or equivalently, the sum \( \sum_{i=1}^{n} Y_i \) of Pareto \( P(a) \) r.v.’s can be approximated by the shifted gamma distribution

\[
G\left( n\lambda^2, \frac{\lambda}{\sqrt{\mathbb{V} Y}}, n\mathbb{E} Y - n\lambda \sqrt{\mathbb{V} Y} \right) = G\left( \frac{n\alpha(\alpha-3)^2}{(\alpha+1)^2(\alpha-2)}, \frac{(\alpha-3)(\alpha-1)}{(\alpha+1)}, \frac{n\alpha(\alpha-1)}{(\alpha+1)(\alpha-2)} \right)
\]

and the value of their distance, \( d_n \), can approximated by the asymptotic upper bound \( D_n^* = \frac{1}{2} \| \varphi \| \beta / n \) (cf. Thm. 3.4). This approximation is demonstrated in Table 5 for \( \alpha = 7 \), where we have also included the exact values of the distances \( d_n \) and \( d_n^N \), which, as in the previous application, were evaluated numerically using Wolfram Mathematica Software. In the same table, we also present the Monte Carlo estimated values \( \hat{x}_n \) of the upper 99.9% level critical points of \( \sum_{i=1}^{n} Y_i \) (using \( 10^6 \) generated samples), along with its shifted gamma (\( x_n^{SG} \), cf. (3.21)) and normal approximation (\( x_n^N \)). As was expected, the shifted gamma approximation outperforms the usual normal approximation.
Table 5. Approximation error estimates ($\alpha = 7$), and upper critical points ($a = 0.001$).

Finally an explicit upper bound for $d_n$ can be derived via Theorem 3.2 (and e.g. $\alpha = 7$) by considering the r.v.'s $X_1, X_2, \ldots$ since $d_1 \approx 0.362 > 1/8$ (cf. Rem. 3.5). By choosing $r = 32$ we compute

$$
\lambda_r = \lambda r^{1/2} \approx 3.34664, \ d_{1,r} \approx 0.00997937, \ \beta_r = \frac{\beta}{r} \approx \frac{0.321429}{32}, \ \varepsilon_r \approx 0.346123.
$$

From Theorem 3.2 we get ($n = rm$)

$$
d_n < \frac{m}{(m-1)^2} \left( \frac{3\beta}{r} \right) + \frac{1}{2}(2d_{1,r})^m \approx 0.046085 \frac{m}{(m-1)^2}, \ m \geq 2. \quad (4.4)
$$

Appendix A.

Proof of Lemma 2.2. The fourth derivative of the p.d.f. of $G(\gamma + 1, 1)$ is equal to

$$
f_{G(\gamma+1,1)}^{(4)}(x) = g_3(x) f_{G(\gamma+1,1)}(x), \text{ where } g_3(x) = \frac{(\gamma-3)(\gamma-2)(\gamma-1)\gamma-4(\gamma-2)(\gamma-1)\gamma x + 6(\gamma-1)\gamma x^2 - 4\gamma x^3 + x^4}{x^4}.
$$

An analytical form of $\|f_{G(\gamma+1,1)}^{(4)}\|$ can be expressed via the roots $\rho_{\gamma,i}, i = 1, 2, 3, 4,$ of the polynomial in $x$ at the nominator of $g_3$. The explicit form of these roots is

$$
\rho_{\gamma,i} = \gamma + r_i \sqrt{\gamma + c_3 + u_3 \sqrt{2\gamma - c_3 + \frac{r_i^2 \gamma}{\sqrt{\gamma + c_3}}}}, \text{ where } c_3 = -\frac{\gamma}{b_\gamma} + \frac{\gamma^2}{b_\gamma} + \frac{b_\gamma}{2},
$$

$$
b_\gamma = 2^{1/3}(\gamma^3 - \gamma^2 + \sqrt{(2 - \gamma)(\gamma - 1)^2 \gamma^2})^{1/3} \text{ and } (r_i, u_3) \text{ equals to } (-1, -1), (-1, 1), (1, -1), (1, 1) \text{ for } i = 1, 2, 3, 4 \text{ respectively. By denoting } \rho_{\gamma,0} = 0, \rho_{\gamma,5} = \infty, \text{ we can express } \|f_{G(\gamma+1,1)}^{(4)}\| \text{ as follows,}
$$

$$
\|f_{G(\gamma+1,1)}^{(4)}\| = \int_0^\infty \left| f_{G(\gamma+1,1)}^{(4)}(x) \right| dx = \sum_{i=1}^5 (-1)^{i+1} \int_{\rho_{\gamma,i-1}}^{\rho_{\gamma,i}} f_{G(\gamma+1,1)}^{(4)}(x)dx = 2 \sum_{i=1}^4 (-1)^{i+1} f_{G(\gamma+1,1)}^{(3)}(\rho_{\gamma,i}).
$$

Unfortunately, the above complicated form cannot be easily upper bounded for all $\gamma$. We shall use an alternative way to find a bound for large $\gamma$. If a r.v. $Z \sim G(\gamma + 1, 1)$, and $\gamma \geq 8$ then,

$$
\|f_{G(\gamma+1,1)}^{(4)}\| = \int_0^\infty \left[ f_{G(\gamma+1,1)}^{(4)}(x) \right] dx = \int_0^\infty |g_3(x)| f_{G(\gamma+1,1)}(x)dx = \mathbb{E} |g_\gamma(Z)| \leq (\mathbb{E} g_\gamma(Z)^2)^{1/2}
$$

$$
= \left( \frac{24(5+\gamma)(42+\gamma)(37+\gamma)}{(\gamma-1)\gamma(\gamma-2)} \right)^{1/2} < \frac{6}{(\gamma+1)^{1/2}}.
$$
where the last inequality is valid for $\gamma \geq 176$. This is true since the only real root of the polynomial
\[
h(\gamma) = 6^2(\gamma - 1) \cdots (\gamma - 7) - (\gamma + 1)^4 24(5 + \gamma)(42 + \gamma(37 + \gamma))
\]
is approximately equal to $\rho = 175.342$ and therefore $h(\gamma) > 0$ for $\gamma > \rho$ (because $h(\gamma) \to \infty$ as $\gamma \to \infty$).
Finally, since $\|f^{(4)}_{G(\gamma + 1,1)}\|$ is a smooth function of $\gamma$ we easily verify numerically that, $\|f^{(4)}_{G(\gamma + 1,1)}\| < 6/(\gamma + 1)^2$ for $8 \leq \gamma < 176$. For the second part of the lemma we observe that $c_\gamma/\gamma \to (1 + \sqrt{3})/2$ as $\gamma \to \infty$, and thus $(\rho,\gamma - \gamma)/\sqrt{\gamma} \to r_i \sqrt{3} + r_i u_i \sqrt{6}$, $i = 1, 2, 3, 4$. Moreover, it can be shown that $f^{(3)}_{G(\gamma,1)}(\gamma + x\sqrt{\gamma})^2 \to \varphi^{(3)}(x)$ as $\gamma \to \infty$, and therefore,
\[
\gamma^2 \|f^{(4)}_{G(\gamma,1)}\| = 2 \sum_{i=1}^{4} (-1)^{i+1} f^{(3)}_{G(\gamma,1)} \left( \gamma + \frac{\rho_{\gamma,i} - \gamma}{\sqrt{\gamma}} \right) \gamma^2 \to 2 \sum_{i=1}^{4} (-1)^{i+1} \varphi^{(3)} \left( r_i \sqrt{3} + r_i u_i \sqrt{6} \right)
\]
which can be easily verified that is equal to $\|\varphi^{(4)}\| = \int_{-\infty}^{\infty} |\varphi^{(4)}(y)| \, dy$.
To complete the proof of parts (a),(b) it finally suffices to observe that
\[
\left\| f^{(4)}_{G(\gamma,\lambda)} \right\| = \int_{0}^{\infty} f^{(4)}_{G(\gamma,\lambda)}(x) \, dx = \int_{0}^{\infty} \lambda^5 f^{(4)}_{G(\gamma,1)}(\lambda x) \, dx = \lambda^4 \int_{0}^{\infty} f^{(4)}_{G(\gamma,1)}(y) \, dy = \lambda^4 \left\| f^{(4)}_{G(\gamma,1)} \right\|. \quad (A.1)
\]
